# 1 Introduction

When writing functional code, we often use functions (or other datastructures) to 'glue' multiple pieces of data together. Take, as an example, the following function in the programming language Haskell, as introduced by Gill et al. (1993):

```
\begin{array}{l} \mathit{all} :: (a \to \mathit{Bool}) \to [\, a\,] \to \mathit{Bool} \\ \mathit{all} \ p = \mathit{and} \circ \mathit{map} \ p \end{array}
```

The function map p traverses across the input list, applying the predicate p to each element, resulting in a new list of booleans. Then, the function and takes this resulting, intermediate, boolean list and consumes it by 'anding' together all the booleans.

Being able to compose functions in this fashion is part of what makes function programming so attractive, but it comes at the cost of computational overhead. We could instead rewrite all in the following fashion:

```
all' p \ xs = h \ xs

where h \ [] = True

h \ (x : xs) = p \ x \wedge h \ xs
```

This function, instead of traversing the input list, producing a new list, and then subsequently traversing that intermediate list, traverser the input list only once, immediately producing a new answer. Writing code in this fashion is far more performant, at the cost of read- and write-ability. Can you write a high-performance, single-traversal, version of the following function (Harper, 2011)?

```
f :: (Int, Int) \to Int

f = sum \circ map (+1) \circ filter \ odd \circ between
```

With some (more) effort, one could arrive at the following solution:

```
\begin{split} f' &:: (Int, Int) \to Int \\ f' &:(x,y) = loop \ x \\ &\quad \text{where } loop \ x \mid x > y = 0 \\ &\quad \mid otherwise = \textbf{if} \ odd \ x \\ &\quad \quad \textbf{then} \ (x+1) + loop \ (x+1) \\ &\quad \quad \textbf{else} \ loop \ (x+1) \end{split}
```

Doing this by hand every time, to get from the nice, elegant, compositional style of programming to the higher-performance, single-traversal style, gets old very quick. Especially if this needs to be done, by hand, **every** time you compose any two functions. Is there some way to automate this process?

Fusion, Category theory, Libfusion paper, church encodings, formalization of it, Haskell's suite of optimizations that enable fusion, (theorems for free?).

# 2 Background

### 2.1 Foldr/build fusion (on lists)

Starting with the basics of fusion. In Gill et al. (1993)'s paper the original 'schortcut deforestation' technique was described. The core idea is described here as follows:

In functional programming lists are (often) used to store the output of one function such that it can then be consumed by another function. To co-opt Gill et al. (1993)'s example:

```
all \ p \ xs = and \ (map \ p \ xs)
```

map p xs applies p to all of the elements, producing a boolean list, and and takes that new list and "ands" all of them together to produce a resulting boolean value. "The intermediate list is discarded, and eventually recovered by the garbage collector" (Gill et al., 1993).

This generation and immediate consumption of an intermediate datastructure introduces a lot of computation overhead. Allocating resources for each cons datatype instance, storing the data inside of that instance, and then reading back that data, all take time. One could instead write the above function like this:

```
all' \ p \ xs = h \ xs

where h \ [] = True

h \ (x : xs) = p \ x \wedge h \ xs
```

Now no intermediate datastructure is generated at the cost of more programmer involvement. We've made a custom, specialized version of and . map p. The compositional style of programming that function programming languages enable (such as Haskell) would be made a lot more difficult if, for every composition, the programmer had to write a specialized function. Can this be automated?

Gill et al. (1993)'s key insight was to note that when using a foldr k z xs across a list, the effect of its application "is to replace each cons in the list xs with k and replace the nil in xs with z. By abstracting list-producing functions with respect to their connective datatype (cons and nil), we can define a function build:

build 
$$g = g(:)[]$$

Such that:

$$foldr \ k \ z \ (build \ q) = q \ k \ z$$

Gill et al. (1993) dubbed this the foldr/build rule. For its validity g needs to be of type:

$$g: \forall \beta: (A \to \beta \to \beta) \to \beta \to \beta$$

Which can be proved to be true through the use of g's free theorem à la Wadler (1989). For more information on free theorems see Section 2.4

## 2.1.1 An example

Take the function from, that takes two numbers and produces a list of all the numbers from the first to the second:

```
\begin{array}{c} from \ a \ b = \mathbf{if} \ a > b \\ \mathbf{then} \ [ \ ] \\ \mathbf{else} \ a : from \ (a+1) \ b \end{array}
```

To arrive at a suitable g we must abstract over the connective datatypes:

```
from' a b = \lambda c n \rightarrow \mathbf{if} a > b

then n

else c a (from (a + 1) b c n)
```

This is obviously a different function, we now redefine from in terms of build (Gill et al., 1993):

```
from \ a \ b = build \ (from' \ a \ b)
```

With some inlining and  $\beta$  reduction, one can see that this definition is identical to the original from definition. Now for the killer feature (Gill et al., 1993):

```
sum (from a b)
= foldr (+) 0 (build (from' a b))
= from' a b (+) 0
```

Notice how we can apply the foldr/build rule here to prevent an intermediate list being produced. Any adjacent foldr/build pair "cancel away". This is an example of shortcut fusion.

One can rewrite many functions in terms of foldr and build such that this fusion can be applied. This can be seen in Figure 1. See Gill et al. (1993)'s work, specifically the end of section 3.3 (unlines) for a more expansive example of how fusion,  $\beta$  reduction, and inlining can combine to fuse a pipeline of functions down an as efficient minimum as can be expected.

```
\begin{split} map \ f \ xs &= build \ (\lambda c \ n \to foldr \ (\lambda a \ b \to c \ (f \ a) \ b) \ n \ xs) \\ filter \ f \ xs &= build \ (\lambda c \ n \to foldr \ (\lambda a \ b \to \mathbf{if} \ f \ a \ \mathbf{then} \ c \ a \ b \ \mathbf{else} \ b) \ n \ xs) \\ xs &+ ys &= build \ (\lambda c \ n \to foldr \ c \ (foldr \ c \ n \ ys) \ xs) \\ concat \ xs &= build \ (\lambda c \ n \to foldr \ (\lambda x \ Y \to foldr \ c \ y \ x) \ n \ xs) \\ repeat \ x &= build \ (\lambda c \ n \to \mathbf{let} \ r = c \ x \ r \ \mathbf{in} \ r) \\ zip \ xs \ ys &= build \ (\lambda c \ n \to \mathbf{let} \ zip' \ (x : xs) \ (y : ys) = c \ (x, y) \ (zip' \ xs \ ys) \\ zip' \ - - = n \\ \mathbf{in} \ zip' \ xs \ ys) \\ [] = build \ (\lambda c \ n \to c \ x \ (foldr \ c \ n \ xs)) \end{split}
```

Figure 1: Examples of functions rewritten in terms of foldr/build. (Gill et al., 1993)

#### 2.1.2 Generalization to any datastructure

This is all well and good, when working with lists, that can be written in terms of foldr's and/or build's (which covers a lot of common functions already), but what if we want to do this for any data structure? Is there a way of generalizing this? The answer is yes\*. \*So long as the datatype we are working with is an initial algebra or terminal coalgebra, and the functions we are working with are instances of cata- or anamorphisms.

What does that even mean?

# 2.2 The category theory

In order to explain what an initial/terminal (co) algebra is, I'll first need to explain what a functor is and, more pressingly, what a category is. The concept of cata- and anamorphisms will follow suit. If you're familiar with category theory and these concepts, you can skip this section.

# 2.2.1 A Category

A category C is a collection of four pieces of data satisfying three proofs:

- 1. A collection of objects, denoted by  $C_0$
- 2. For any given objects  $X, Y \in \mathcal{C}_0$ , a collection of morphisms from X to Y, denoted by  $hom_{\mathcal{C}}(X, Y)$ , which is called a *hom-set*.
- 3. For each object  $X \in \mathcal{C}_0$ , a morphism  $\mathrm{Id}_X \in \mathrm{hom}_{\mathcal{C}}(X,X)$ , called the identity morphism on X.
- 4. A binary operation:  $(\circ)_{X,Y,Z} : \hom_{\mathcal{C}}(Y,Z) \to \hom_{\mathcal{C}}(X,Y) \to \hom_{\mathcal{C}}(X,Z)$ , called the *composition operator*, and written infix without the indices X,Y,Z as in  $g \circ f$ .

These pieces of data should satisfy the following three properties:

1. (**Left unit law**) For any morphism  $f \in hom_{\mathcal{C}}(X,Y)$ :

$$f \circ \mathrm{Id}_X = f$$

2. (**Right unit law**) For any morphism  $f \in hom_{\mathcal{C}}(X, Y)$ :

$$\mathrm{Id}_Y \circ f = f$$

3. (Associative law) For any morphisms  $f \in hom_{\mathcal{C}}(X,Y), g \in hom_{\mathcal{C}}(Y,Z),$  and  $h \in hom_{\mathcal{C}}(Z,W)$ :

$$h\circ (g\circ f)=(h\circ g)\circ f$$

# 2.2.2 Initial/Terminal Objects

Categories can contain objects that have certain (useful) properties. Two of these properties are summarized below:

initial Let  $\mathcal{C}$  be a category. An object  $A \in \mathcal{C}_0$  is initial if there is exactly one morphism from A to any object  $B \in \mathcal{C}_0$ :

$$\forall A, B \in \mathcal{C}_0 : \exists ! hom_{\mathcal{C}}(A, B) \Longrightarrow \mathbf{initial}(A)$$

**terminal** Let C be a category. An object  $A \in C_0$  is **terminal** if there is exactly one morphism from any object  $B \in C_0$  to A:

$$\forall A, B \in \mathcal{C}_0 : \exists ! hom_{\mathcal{C}}(B, A) \Longrightarrow \mathbf{terminal}(A)$$

The proofs of initality and terminality require a proof that is split into two steps: A proof of existence (The  $\exists$  part of  $\exists$ !) and a proof of uniqueness (The ! part of  $\exists$ !). The former is usually done by construction, giving an example of a function that satisfies the property and the latter is usually done my assuming that another  $\mathsf{hom}_{\mathcal{C}}(A, B)$  (for the initial case) exists and showing that it must be equal to the one constructed.

#### 2.2.3 Functors

For a given category  $\mathcal{C}, \mathcal{D}$ , a functor from  $\mathcal{C}$  to  $\mathcal{D}$  consists of two pieces of data and three proofs:

1. A function mapping objects in  $\mathcal{C}$  to  $\mathcal{D}$ :

$$\mathcal{C}_0 \to \mathcal{D}_0$$

2. For each  $X, Y \in \mathcal{C}_0$ , a function mapping morphisms in  $\mathcal{C}$  to morphisms in  $\mathcal{D}$ :

$$\hom_{\mathcal{C}}(X,Y) \to \hom_{\mathcal{D}}(F(X),F(Y))$$

These pieces of data should satisfy these two properties:

1. (Composition law) for any two morphisms  $f \in \text{hom}_{\mathcal{C}}(X,Y), g \in \text{hom}_{\mathcal{C}}(Y,Z)$ :

$$F(q \circ f) = Fq \circ Ff$$

2. (**Identity law**) For any  $X \in \mathcal{C}_0$ , we have:

$$F(\mathrm{Id}_X)=\mathrm{Id}_{F(X)}$$

An **endofunctor** is a functor that maps objects back to the category itself, i.e.  $F: \mathcal{C} \to \mathcal{C}$ 

### 2.2.4 (Category of) F-(Co)Algebras

Given an endofunctor  $F: \mathcal{C} \to \mathcal{C}$ :

An **F-Algebra** consists of two pieces of data:

- 1. An object  $C \in \mathcal{C}_0$
- 2. A morphism  $\phi \in hom_{\mathcal{C}}(F(C), C)$

An **F-Algebra Homomorphism** is, given two F-Algebras  $(C, \phi), (D, \psi)$ , a morphism  $f \in \text{hom}_{\mathcal{C}}(C, D)$ , such that the following diagram commutes (i.e.  $f \circ \phi = \psi \circ Ff$ ):

$$FC \xrightarrow{\phi} C$$

$$Ff \downarrow \qquad \qquad \downarrow f$$

$$FD \xrightarrow{\psi} D$$

The category of F-Algebras denoted by Alg(F) consists of (the needed) four pieces of data:

4

1. The objects are F-Algebras

- 2. The morphisms are F-Algebra homomorphisms
- 3. The identity on  $(C, \phi)$  is given by the identity  $Id_C$  in C
- 4. The composition is given by the composition of morphisms in C

These pieces of data should satisfy the usual category laws: left/right unit law and composition law. Note how  $\mathcal{A}lg(F)$  makes use of the underlying category  $\mathcal{C}$  of the functor to define its objects. An  $\mathcal{A}lg(F)$  implicitly contains an underlying category in which its objects are embedded.

An **F-Coalgebra** consists of two pieces of data:

- 1. An object  $C \in \mathcal{C}_0$
- 2. A morphism  $\phi \in \text{hom}_{\mathcal{C}}(C, F(C))$

F-Coalgebra homomorphisms and CoAlg(F) can be defined analogously as done for F-Algebras.

#### 2.2.5 Cata- and Anamorphisms

Given (if it exists) an initial F-Algebra  $(\mu^F, in)$  in  $\mathcal{A}lg(F)$ . We can know that (by definition), that for any other F-Algebra  $(C, \phi)$ , there exists a unique morphism  $(\phi) \in \mathsf{hom}_{\mathcal{C}}(\mu^F, C)$  such that the following diagram commutes:

$$F\mu^F \xrightarrow{in} \mu^F$$

$$F(\phi) \downarrow \qquad \qquad \downarrow (\phi)$$

$$FC \xrightarrow{\phi} C$$

A morphism of the form  $(\phi)$  is called a **catamorphism**.

An analogous definition of for terminal objects in CoAlg(F) exists, called **anamorphisms**, denoted by  $\llbracket \phi \rrbracket$ 

#### 2.2.6 Fusion property

Now for the definition we've been waiting for, **fusion**: Given an endofunctor  $F: \mathcal{C} \to \mathcal{C}$  and an initial algebra  $(\mu^F, in)$  in  $\mathcal{A}lg(F)$ . For any two F-Algebras  $(C, \phi)$  and  $(D, \psi)$  and morphism  $f \in \mathsf{hom}_{\mathcal{C}}(C, D)$  we have a **fusion property**:

$$f \circ \phi = \psi \circ F(f) \Longrightarrow f \circ (\phi) = (\psi)$$

In English, if f is an F-Algebra homomorphism, we can know that  $f \circ (\psi) = (\psi)$ . We can fuse two functions into one! This is summarized in the following diagram:

$$F\mu^{F} \xrightarrow{in} \mu^{F}$$

$$F(\psi) \qquad \qquad \downarrow (\phi) \qquad \qquad \downarrow (\psi)$$

$$FC \xrightarrow{\phi} C \qquad \qquad \downarrow f \qquad \qquad \downarrow f$$

$$FD \xrightarrow{\psi} D \qquad \qquad \downarrow f$$

An analogous definitions of fusion can be made for terminal object in CoAlg(F)

# 2.3 Library Writer's Guide to Shortcut Fusion

Gill et al. (1993)'s work has been built upon in several ways:

One work that attempts to clearly explain a generalized form of Gill et al. (1993)'s work is "A Library Writer's Guide to Shortcut Fusion" by Harper (2011).

In the work, Harper (2011) explain the concept of Church and CoChurch encodings in three steps:

1. Explaining the mathematical background of Category theory, including F-Algebras, Fusion, and

5

#### 2.4 Theorems for Free

### 2.5 Containers

### 3 Formalization

In Harper (2011)'s work "A Library Writer's Guide to Shortcut Fusion", the practice of implementing Church and CoChurch encodings is described, as well a paper proof necessary to show that the encodings optimizations employed are correct.

In this section the work I have done to formalize these proofs in the programming language Agda is discussed, as well as additional proofs to support the claims made in the paper.

The code can be neatly presented in roughly 2 parts:

- The proofs of the category theory truths described by Harper (2011).
- The proofs about the (Co)Church encodings, again as described by Harper (2011).

# 3.1 Category Theory Formalization

#### 3.1.1 funct

This module contains some simple definition, utilized in both complimentary structures (cata-/anamorphisms, church/cochurch).

**Functional Extensionality** We postulate functional extensionality. This is done through Agda's builting Extensionality module:

```
module agda.funct.funext where open import Axiom.Extensionality.Propositional postulate funext : \forall \{a\ b\} \rightarrow Extensionality a\ b funexti : \forall \{a\ b\} \rightarrow ExtensionalityImplicit a\ b funexti = implicit-extensionality funext
```

**Endofunctors** An endofunctor is defined across the category of agda sets, where the functors are interpretations of containers. There is a little bit of unwieldyness as Sets defines equality through extensionality, but using an implicity parameter. In order to combine it with **funext** little bit of unpacking and repacking of the definitions needs to be done.

```
module agda.funct.endo where open import Data.Container using (Container; [-]; map) open import Level using (0\ell) open import Categories.Category.Instance.Sets using (Sets) open import Categories.Functor using (Endofunctor) open import Relation.Binary.PropositionalEquality open \equiv-Reasoning open import agda.funct.funext using (funext) open import Function  F[-]: (F: \text{Container } 0\ell \ 0\ell) \rightarrow \text{Endofunctor } (\text{Sets } 0\ell) \\ F[F] = \text{record } \{F_0 = [F]] \\ ; F_1 = \text{map} \\ ; \text{identity} = \text{refl} \\ ; \text{homomorphism} = \text{refl} \\ ; F-\text{resp-} \approx = \lambda \ p \rightarrow \text{cong}_2 \ \text{map } (\text{funext } (\lambda \ x \rightarrow p \ \{x\})) \ \text{refl} \\ \}
```

#### 3.2 init

This module contains the definitions needed to define catamorphisms and prove its categorical fusion.

```

# 4 Haskell Optimizations

In Harper (2011)'s work there were still multiple open questions left regarding the exact mechanics of what Church and Cochurch encodings did while making their way through the compiler. Why are Cochurch encodings faster in some pipelines, but slower in others? etc.

In this section I'll describe my work replicating the fused Haskell code of the Harper (2011)'s work and further optimization opportunities that were discovered along the way.

# 4.1 Church encodings

### 4.2 Cochurch encodings

# 5 Outline

- Introduction
- Background
- Formalization work and structure
- Implementation of Haskell generator code?
- Conclusion

# 6 Project plan

- Harper (2011)'s guide for implementing shortcut fusion through Church encodings is useful. This paper aims to do the following:
  - Formalize the proofs present in Harper (2011)'s work in Agda.
  - Investigate whether it is possible to mechanically generate Church encodings of arbitrary functors (initial algebra datastructures) in Haskell.
